Introduction

To develop more equitable beach access, including beach improvement projects and additional beach access locations and facilities, it is critical to better understand public beach users and patterns of beach use. While a significant amount of visitor data has been collected over the years in southern California, the extent, scope, and completeness of current public beach access and usage data remains incomplete and is insufficient to support more complete analysis and to adequately inform better management and stewardship.

The Beach Erosion Authority for Clean Oceans and Nourishment (BEACON), along with its project partners—the Mountains Recreation and Conservation Authority (MRCA), California State University Channel Islands (CSUCI), the USEPA Office of Research and Development (ORD), and The Bay Foundation (TBF)—formed the "Cellphone Data Working Group." This group developed a pilot project to address a data and research gap concerning beach visitation and use. The project specifically utilizes commercially available datasets of visitation based on cellphone locations, referred to as "cellphone-derived location data."

Recent studies on visitation to parks and beaches show that cellphone-derived location data can produce accurate estimates of daily and monthly visitation counts (Merrill et al., 2020; Monz et al., 2021; Monz et al., 2019). This pilot project aims to leverage cellphone-derived location data to estimate beach visitation, understand large-scale beach use patterns, and collect information on the origin and demographics of visitors. The Cellphone Data Working Group selected 50 discrete coastal access sites in southern California for evaluation, spanning from western Santa Barbara County to Santa Monica Bay and covering three counties: Santa Barbara, Ventura, and Los Angeles.

This technical methods memo outlines the research and analysis methods used in the pilot project for selected regional beaches. It addresses key topics such as the use and processing of private vendor mobility data, the integration of publicly available demographic data, and the incorporation of this data into GIS decision-support tools. The Cellphone Data Working Group's initial research and analysis suggest that cellphone location-derived mobility data is a valuable addition to current beach use and user information, under specific conditions. Obtaining this data requires a financial commitment, multidisciplinary trained personnel, and multiple technical data processing and integration steps to combine it with demographic data. Additionally, mobility data must be incorporated into an ongoing beach user monitoring program, supported by traditional on-the-ground beach count information, to ensure its representativeness and consistency.

Background

For more than 50 years, maximizing public beach access has been an important goal of integrated coastal zone management in California. This goal has become increasingly significant in the context of environmental and social justice in coastal policy and programs. Political contests over public beach access has remained a central feature of the deliberations and actions of the California Coastal Commission since its inception in the 1970s. Most recently, public beach access is emerging as a significant contemporary coastal management battleground, with Martin's Beach, Hollister Ranch, and Malibu being synonymous with inequitable access to the coast.

BEACON has utilized the best available social science, including data on beach use and beach users, as an essential component of advancing practice and addressing the many barriers to coastal access for the past several decades. Despite this, social science data collection efforts have been very limited, receiving only minimal attention and funding over the years (Christensen & King, 2017; Colgan et al., 2021; King, 1999, 2002; King & McGregor, 2012; King & McGregor, 2013; King & Symes, 2004; King, 2001, 2006; Lester et al., 2023; Nelson et al., 2007; Patsch et al., 2021; Pendleton & Kildow, 2006; Pendleton et al., 2011). BEACON and other public agencies use various methods to collect beach use information to improve beach management (Table 1).

In our region of interest, user surveys were conducted periodically across different coastal beach locations, but comprehensive regional and statewide data is still lacking. Recent efforts addressed some of this gap (Christensen & King, 2017; King, 2002; King & McGregor, 2012; King & McGregor, 2013). Christensen and King (2017) conducted over 1,000 intercept surveys at southern California beaches and collected data from a statewide voter poll. Currently, as of Fall 2024, CSUCI is completing a three-year long study, The Beach Sustainability Assessment (BSA) that involves collecting socioeconomic data from in-person surveys, latent demand surveys, and focus groups to identify barriers to coastal access in Santa Barbara and Ventura counties. Thus far, the BSA has collected over 1,200 intercept surveys, conducted six regional focus groups, and completed a regional latent demand survey on beach users and local community members to better understand beach visitation and access as part of a project funding jointly by the CSU Council on Ocean Affairs, Science, and Technology (COAST) and California Sea Grant as part of the State Science Information Needs Program (SSINP).

Table 1. Traditional Methods of Beach User Data Collection

Method	Regional Example	Visitor Use Dimensions
Observational studies	Lifeguard counts, Beach Sustainability Assessment (Patsch et al., 2021) Who's counting: An analysis of beach attendance estimates and methodologies in southern California (King & McGregor, 2012)	counts, transportation
Intercept Surveys	BEACON Intercept Beach Survey (King & McGregor, 2013) Beach Sustainability Assessment (BSA) Access for All (Christensen & King, 2017)	origins, demographics, spending, amenity preferences, transportation
Traffic and Parking		counts, transportation, operation revenue, origins
Latent Demand Studies	Access for All (Christensen & King, 2017)	origins, demographics, spending, amenity preferences, transportation

Notwithstanding these efforts, practitioners and researchers need additional beach use and beach user data and information. Each of these methods individually is limited in the visitor use dimensions collected (count of visitors, origin of visitors, demographics, etc.), geographically constrained, and/or limited in the time and type of visitors they represent. Additionally, these programs are resource-intensive and complicated to maintain for long-term or large-scale monitoring.

For these same reasons, common to other natural land visitor monitoring efforts, practitioners and researchers explored the use of alternative methods (Leggett, 2017; Liang et al., 2022; Mashhadi et al., 2020; Mazzotta et al., 2021; Merrill et al., 2020; Monz et al., 2021; Monz et al., 2019; Narragansett National Estuary Program, 2021; Wilkins et al., 2021; Yoo et al., 2020; Zandbergen, 2009). These methods include using social media, imagery from satellites and aircraft, and cellphone locational data (Table 2), and promise the ability to infer similar visitor use dimensions passively over a larger geography and time, potentially offsetting the considerable expenses of more traditional methods.

Table 2. Emerging Methods for Beach User Data Collection

Method	Example	Visitor use dimensions
Social Media	Woods et al. (2013)	Counts, origins, demographics, amenity preferences
Cellphone-derived location data	Merrill et al. (2020)	Counts, origins, demographics
Satellite and aerial imagery	Tourangeau et al. (2017)	Counts
Tech-Enabled Citizen Science	Lia et al. (2023)	Counts, origins, demographics, amenity preferences

Alternative methods show effectiveness in estimating visitation counts in a variety of settings including at beaches and parks (see Table 2); however, they are best paired with traditional methods to create estimates on a similar scale to on-the-ground observations and to ensure stability of relationships over time (Merrill et al., 2020; Wilkins et al., 2021). The utility and accuracy of other inferences based on these emerging data methods, such as estimating demographic makeup of visitors (Liang et al., 2022; Mashhadi et al., 2020; Monz et al., 2021; Monz et al., 2019) or economic value (Sinclair et al., 2020) are areas of active research.

Cellphone-derived locational data, or mobility data, the focus of this pilot project, comes in a variety of styles and formats and the industry is evolving quickly. Most of the currently available products are based on device locations of smartphones collected by applications installed on the phone. These device locations are sold by application software developers to data companies that aggregate this information across many sources, remove personally identifiable information, and process this data to visitation-relevant metrics, such as foot traffic and visitor origins. There are numerous private companies offering various levels of processing away from the raw device locations as well as different derived products to fit specific needs, like road traffic, density of human use across space, or visitor origins. It is in no way standardized or a consistent product space (Whitney et al., 2023). Visitation inferences based on one product are not likely to translate to others directly (Whitney et al., 2023). For this report, cellphone-derived locational data was purchased from [AirSage](https://airsage.com/) (<https://airsage.com/>), a transportation data vendor.

Data

The promise of cellphone-derived location data for visitor use monitoring is in the ability to cover a large geographic scale at a range of temporal scales (e.g. hourly, daily, monthly, years). The Cellphone-data Working Group chose the beach sites to sample, referred to as “points of interest” or “POIs”, based on many factors, including regional location of the beaches, from urban settings to more rural settings; a range of beach sizes, including smaller, medium, and larger beaches; beaches with a range of amenities and facilities; historical use; beach locations involving a range of beach management agencies; as well as beaches with ongoing complementary research. The beach sites represent popular and often, very well

used, public beaches in the three counties (Figure 1). The beach locations chosen (Figure 1) are managed by more than a dozen agencies and under a broad range of conditions. The pilot project sites are identified by county and management agency in Table 3.

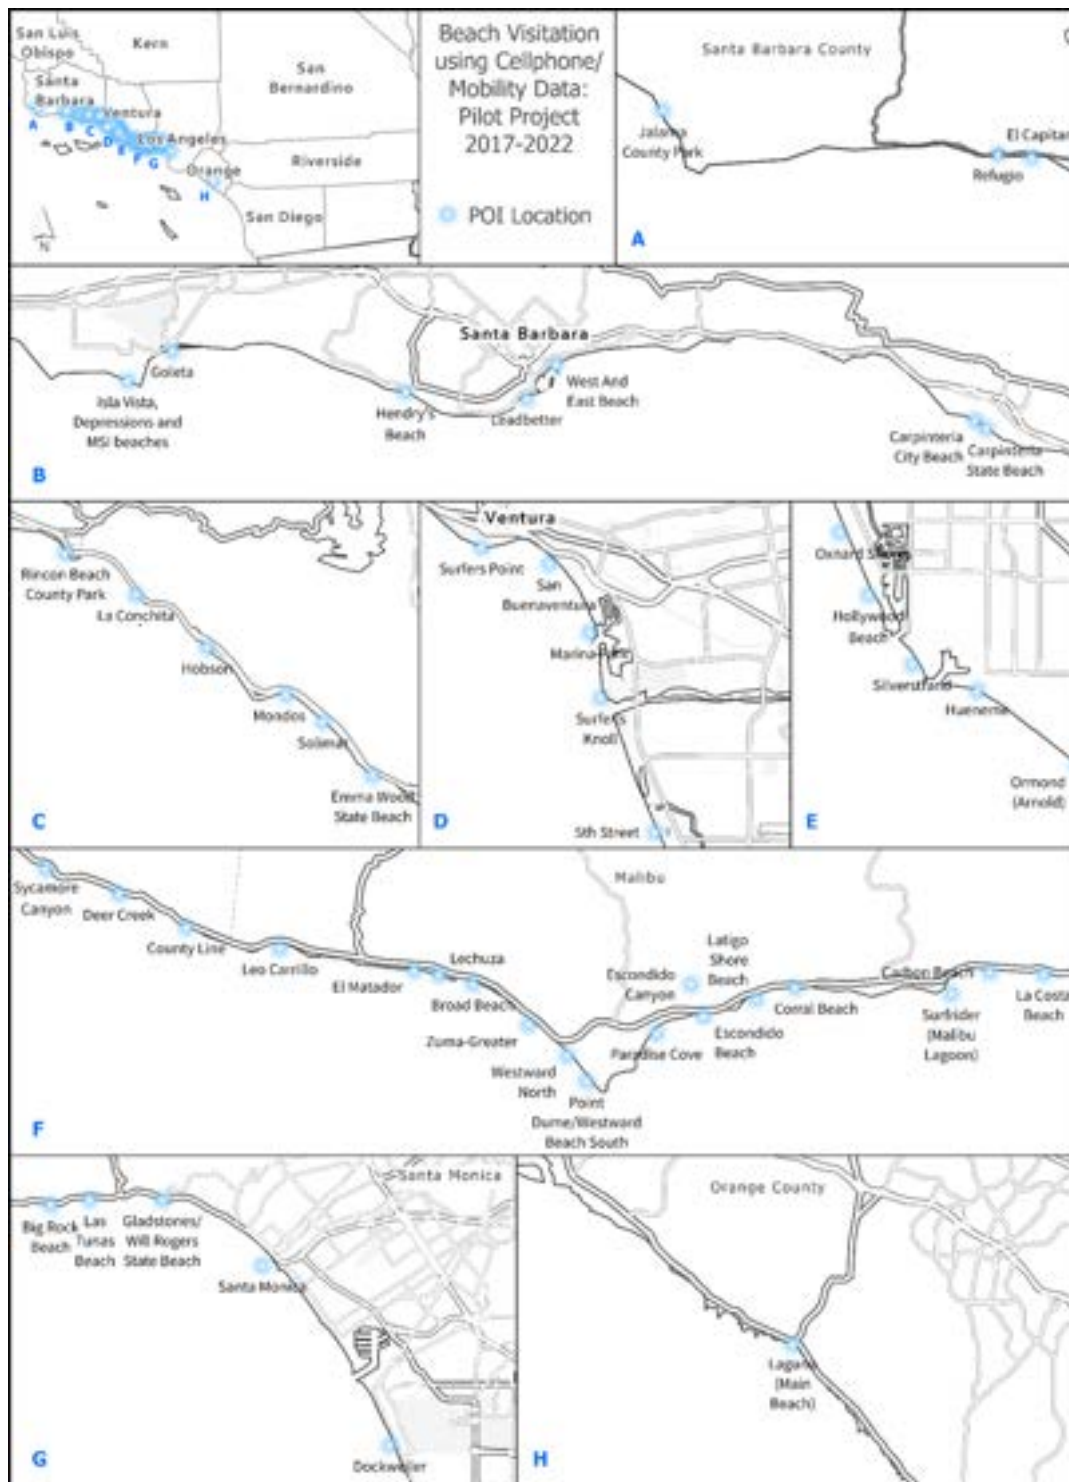

Figure 1. Location of Pilot Beach Sites (also known as Points of Interest (POIs)). H* Laguna Beach, in Orange County, is part of the BSA and used for data validation.

To delineate each beach, the Cellphone Data Working Group manually digitized geographic areas (polygons) representing site locations using ArcGIS Pro and a 2021 orthorectified basemap provided by esri. Boundary lines were extended oceanward into the nearshore environment to capture visitors recreating in the water and account for changes in seasonal beach width. Leveraging expert knowledge and collaborative reviews, the group included regions where beach-related recreation occurs, such as sandy areas, nearby boardwalks, and grassy areas. Built environments, such as restaurants and private homes, were intentionally excluded. Where appropriate, the parking resources for each beach within the polygons were digitized, as relating parking availability to beach attendance is of interest. These areas were similarly defined with expert input and team reviews. For this pilot project, the polygon areas were limited to day-use beach areas and day-use parking and excluded piers as well as overnight campgrounds. In some cases, only a portion of the beach, not the complete beach access area, was delineated. All digitized beach and parking polygons can be seen in the Appendix.

The vendor, AirSage, provided datasets inferring total hourly and daily visitation as well as visitor origins at a daily, census block group resolution for each POI during the study period from 2017 to 2022. Specifically, for every hour of every day from January 1, 2017, to December 31, 2022, the dataset includes a summary of the number of people on the beach within each POI polygon. Additionally, it provides daily unique visitor counts and a daily summary of how many visitors' home locations were in a particular census block group.

AirSage derives its aggregated visitation information from a panel of cellular device locations, built from data collected via multiple smartphone applications. The terms of use agreements of AirSage and similar companies do not disclose the specific applications providing these

locations. AirSage advertises a panel representing the movement of about one-third of all US citizens (over 100 million people) each month (AirSage, 2021).

AirSage processes this device-level locational data to produce the aggregate summaries provided. To estimate visitation to a given POI in a given timeframe, AirSage first defines the origin (census block group) of the device based on its location on weeknights throughout the month of interest. Work locations are similarly defined by the device locations during daytime hours on weekdays (AirSage, 2021). Using estimates of the number of devices in its location panel as a proportion of the total population of the census tract, AirSage assigns an extrapolation factor for each device, similar to commonly used survey-to-population estimation methods with other instruments.

In AirSage's panel, visits by devices are considered activity points, excluding where the POI is defined as a home or work location. AirSage then sums the activity points and creates unique device counts for the timeframe based on the set of devices observed (AirSage, 2021). The count of unique device visits in a day is conceptually the visitation metric typically desired for analysis, as that count proxies what would have been collected with a gate count. Instead of a physical gate, the "gate" is the geo-fence or the POI geography.

The Cellphone Data Working Group focused on inferring the demographics of beach visitors using cellphone-derived location data methods. This need is critical for beach managers, as it has significant implications for the equitable management of coastal resources. Research in this area is still developing (Liang et al., 2022; Mashhadi et al., 2020; Monz et al., 2021; Monz et al., 2019). AirSage's product includes demographic inferences based on the origin of visitors by linking the demographics of the census block group derived from the 2010 US Census to each visitor based on their home origin. This allows AirSage to create a panel-weighted demographic profile for each POI and timeframe.

Methods

Using the cellphone-derived location data purchased from AirSage for the 51 POIs in this pilot project, summaries of beach use were created by summing daily visitation estimates for each POI and timeframe of interest, including monthly and yearly totals. Visitation by origin was then disaggregated by "home" geography at the census block group level, organizing the data into tables for future analysis, plotting, and mapping.

Previous work with cellphone-derived location data and beach visitation found the data useful for estimating daily visitation but noted that it does not always align in scale with traditionally collected visitation series (Merrill et al., 2020; Tsai et al., 2023). Therefore, as a first step in this pilot project, the cellphone-derived visitation data was compared against existing ground-collected visitation data. For the BEACON region, the only contemporaneous series to the cellphone data timeframe that is both available and willingly shared are the visitation counts taken as part of a long-term beach monitoring protocol by the Environmental Science and Resource Management faculty at CSUCI since 2013 and is now part of the BSA (Patsch et al., 2021).

The BSA at CSUCI not only serves to assess the condition of California's sandy beach ecosystems but also acts as a valuable source of standardized environmental data collection. The BSA index is computed from three primary attribute scores: ecological functioning, geomorphology, and social utility. Each of these attribute scores is derived from an aggregation of various metric scores that measure specific aspects of beach health and usability.

In addition to providing detailed scores and grades for each component—geomorphological, ecological functioning, and social utility—the BSA also synthesizes these components into a single, overarching grade for each beach. This holistic approach to beach assessment ensures a comprehensive evaluation that supports the sustainable management and conservation of beach environments (Patsch et al., 2021).

Funded annually, when resources permit, the BSA conducts environmental assessments across approximately 60 beach sites during the peak summer months of June and July (Patsch et al., 2021). A crucial part of these assessments is the collection of visitation data through instantaneous counts of people present at the beach sites, following a standardized protocol to ensure consistency and reliability across all surveyed locations (Figure 2). This direct observation method complements other data collection strategies and provides immediate, empirical insights into beach usage patterns.

The figure displays two side-by-side screenshots of a mobile application interface for a survey titled "My Survey".

The left screenshot shows a section titled "People using the Beach". It contains seven questions, each followed by a numeric input field (showing "0") and a circular icon with an "X":

- How many people are sun bathing? *
- How many people are wading/swimming? *
- How many people are fishing? *
- How many people are surfing? *
- How many people are kite surfing? *
- How many people are walking/running (for recreation)? *
- How many people are digging/making sand castles? *

The right screenshot shows a section titled "Parking". It contains three questions, each followed by a numeric input field (showing "0") and a circular icon with an "X":

- How many parking spaces are in the lot? *
Yes, you have to count them all!
- How many cars are parked in the lot? *
Yes, you have to count them all!
- How many cars are parked on the road? *
Yes, you have to count them all!

Below these questions is a prompt "Take a photo of the parking lot" and two icons: a camera and a folder.

Figure 2: Example data collection survey instrument showing collection of social utility data at beaches as part of the Beach Sustainability Assessment (Patsch et al., 2021).

The integration of BSA on-the-ground counts with cellphone-derived location data offers a nuanced approach to understanding beach visitation patterns. While BSA counts provide instantaneous snapshots of visitor numbers, the counts differ from gate counts that track unique visitors throughout the day. Nonetheless, these counts offer valuable glimpses that can be effectively paired with the continuous, albeit indirect, data from cellphones.

To align these two data types—BSA instantaneous counts and cellphone-derived hourly visitation estimates—we employed a three-hour averaging technique for the cellphone data. This approach accounts for the variability in BSA survey times, which typically last 2-3 hours, and mitigates issues such as data censoring and small sample sizes that can lead to zero visitation estimates in certain hourly intervals. By averaging over a three-hour window, we smooth these fluctuations to better approximate the actual visitor presence during the broader time period.

This method also compensates for the inherent uncertainty in the exact timing of BSA counts, as the counting process can extend beyond a single hourly interval, potentially overlapping with periods before and after the actual count. By using a three-hour average for cellphone data, we create a more robust comparison framework that more accurately reflects the visitor dynamics captured in the BSA counts.

To analyze the relationship between the BSA visitation/people counts and cellphone-derived visitation data, we employed various statistical methods. Scatter plots visualize data distribution and assess alignment, scale relationships examine correspondence in magnitude, and Pearson correlation coefficients quantify the linear association between datasets across different times and locations.

Analyzing each beach, or point of interest (POI), separately allowed us to identify specific patterns and discrepancies, that aids in tailoring management strategies for beach visitation.

In addition to these analyses, we estimated the demographics of beach visitors using cellphone-derived home census block group location data. While individual visitors may not directly reflect the average demographics of their census block groups, aggregating these data can provide a reasonable approximation of visitor demographics (Liang et al., 2022; Mashhadi et al., 2020; Monz et al., 2021; Monz et al., 2019). Dissatisfied with the outdated 2010 Census information aggregated and offered with the AirSage data, we instead connected each visitor's origin, or home census block group, to the more recent 2020 Census data. This allowed us to create panel-weighted demographic profiles for each POI, focusing on demographic dimensions relevant to our research needs. This approach enhances our understanding of visitor demographics, supporting more equitable and informed management of beach resources. We cross walked the census race and ethnicity categories using the following logic outlined in Table 4 to better capture the difference between people who identified as white alone and/or Hispanic/Latino/a/x/e (US Census, 2010; US Census, 2020; US Census Bureau, 2023).

Table 4. Comparing Vendor Demographic Data with the Cellphone data Working Group's Demographic and Ethnic Categories based on the 2020 US Census.

AirSage Vendor Data from 2010 Census Data	Cellphone Data Working Group's 2020 Census Data Race and Ethnic Categories
-----	Hispanic or Latino/a/x/e
White	White alone, non-Hispanic
Black	Black or African American alone, non-Hispanic
Native American	American Indian or Alaskan Native alone, non-Hispanic
Asian	Asian alone, non-Hispanic
Hawaiian Pacific	Native Hawaiian or Other Pacific Islander Alone, Non-Hispanic
Other	Some other Race Alone, non-Hispanic
Two With Other	Multiracial (two or more races), non-Hispanic

Additionally, we sought to summarize visitation by origin geography, or home census block group, to understand the proportion of visitors coming from disadvantaged or vulnerable communities. Various metrics identify vulnerability and level of disadvantage, including (but not limited to):

- **Low-Income Communities:** Areas where resident incomes are below the federal poverty level or where many households experience financial hardship. Indicators include poverty rates and median household income.
- **Environmental Justice Communities:** Communities where minority and low-income populations disproportionately bear the burden of environmental pollution and hazards, leading to adverse health impacts.
- **Rural and Remote Communities:** Communities with limited access to essential services and resources, facing challenges related to geographic isolation and limited infrastructure.
- **Communities of Color:** Areas with a high proportion of racial and ethnic minority residents who face systemic discrimination and disparities in access to essential services.
- **Historically Underserved Communities:** Communities that have faced historical and systemic barriers to economic, social, and political opportunities, including Indigenous and Black/African American communities.
- **High-Risk or Vulnerable Populations:** Groups such as children, elderly individuals, individuals with disabilities, and those experiencing homelessness or housing insecurity, who are at increased risk of adverse outcomes.

These definitions guide policy, research, and programs to address disparities and promote equity and inclusion. Assessing metrics of vulnerability, their efficacy, and delineation is an active area of research (Birkman, 2013; Buckingham et al., 2021; Buckle et al., 2000; Chang et al., 2015; Dunning & Durden, 2013; Polsky et al., 2007; Schweikert et al., 2018; Spielman et al., 2020). For this pilot project, we aimed to use the best available data relevant to coastal resource visitation.

Senate Bill 535² mandates that California's disadvantaged communities are identified for state climate investments through criteria that include geographic, socioeconomic, public health, and environmental hazard factors. Specifically, these communities are characterized by a combination of high pollution burdens, low income, high unemployment rates, low home ownership levels, high rent burdens, and low educational attainment.

Several indices have been developed to identify disadvantaged, vulnerable, under-resourced, and/or underserved populations, typically at the census tract level. These include (but are not limited to):

- [National Environmental Justice Screening and Mapping Tool \(EJSCREEN\)](#) (US EPA, 2024)
- [Social Vulnerability Index \(SVI\)](#) (US Climate Resilience, 2024)
- [California EnviroScreen 3.0 and 4.0](#) (OEHHA, 2024)
- [Environmental Justice Index \(EJI\)](#) (US. Department of Health and Human Services, 2024)
- [US Department of Transportation's Climate and Economic Justice Screening Tool \(CEJST\)](#) (US Department of Transportation, 2024)

After analyzing the variables and metrics used in these tools, we chose California EnviroScreen 4.0 (August et al., 2021; OEHHA, 2024) for our analysis, to provide the most comprehensive and relevant data for California coastal access and equity. California EnviroScreen 4.0 is recommended for use by the California Environmental Protection Agency (2022) pursuant to Senate Bill 535.

California EnviroScreen 4.0 is a tool developed by the California Environmental Protection Agency's Office of Environmental Health Hazard Assessment (OEHHA) to identify communities disproportionately burdened by multiple sources of pollution and socioeconomic vulnerabilities (August et al., 2021). The tool uses various indicators to assess community vulnerability, including:

1. **Environmental Pollution Burden:** Exposure to pollutants like air and water pollution and hazardous waste facilities.
2. **Socioeconomic Vulnerability:** Factors such as income levels, unemployment rates, educational attainment, linguistic isolation, and housing status.
3. **Public Health Indicators:** Rates of health conditions like asthma and cardiovascular disease associated with environmental exposures.
4. **Cumulative Impact:** The combined effects of multiple pollution sources and socioeconomic vulnerabilities.

² SB 535 represents a significant effort to advance environmental justice and promote equitable development in California. By targeting investments in disadvantaged communities, the bill seeks to address longstanding environmental disparities and empower communities to build healthier, more sustainable futures.

California EnviroScreen 4.0 aims to identify communities most in need of targeted interventions and resources to address environmental disparities and promote environmental justice (August et al., 2021).

The data provided by AirSage, binned by census block group, can be joined to a Geographic Information System (GIS) to summarize census tract boundaries and to assess using other geospatial vulnerability indices.

Results

With the cellphone-derived visitation and location data products provided as a comma-separated values (CSV) file by AirSage, the data was aggregated and summarized by beach, hour, day, month, year, and census block group. The data was then joined to a Geographic Information System (GIS) to further analyze visitor origins and demographics using simple spatial joins and summarizing operations. This information was provided at a high spatial (beach-specific) and temporal resolution (up to hourly), matching the needs of beach managers and researchers. However, more research is needed to understand the alignment with ongoing traditional methods in terms of scale.

Case Study 1: Goleta Beach

Goleta Beach County Park, located in Santa Barbara County, is a popular coastal destination known for its recreational amenities. Situated just east of the University of California, Santa Barbara, this 29-acre park features a long sandy beach, grassy picnic areas, a fishing pier, and a boat launch (Figure 3). As a key recreational site, Goleta Beach County Park serves a diverse range of visitors from the local community and beyond, providing an ideal location for studying beach visitation patterns and understanding the dynamics of public access to coastal resources.

Figure 3: Goleta Beach County Park, Santa Barbara in 2023, Google Earth Image

As the goal of this study is to understand beach use, the POI polygon was drawn to include the beach and parking areas while excluding the fishing pier and restaurant (Figure 4).

General statistics about visitation within this polygon were then calculated. From 2017 to 2022, 2.9 million people visited Goleta Beach, with an average visitation of nearly 500,000 people per year (Figure 5). Most of the visitors' home origins are in Santa Barbara County, with a lesser percentage from Los Angeles, Ventura, Orange, and San Diego counties respectively (Figures 6 and 7).

For Goleta Beach, the most popular month for visitation is June, the most popular day of the week is Sunday, and the average visitor stay is 1.25 hours. The busiest hour at this beach is 4:00 pm. Additionally, nine percent of the visitors to this beach live in a census tract determined by California EnviroScreen 4.0 to be in the top 30% most vulnerable or disadvantaged in California (Figure 8). Using the breakdown of demographics by census block group, an estimated 48% of visitors to Goleta Beach identify as white, not Hispanic, 34% identify as Hispanic or Latino/a/e/x, and 18% as some other race or a combination of races, not Hispanic (Figure 9). Graphics and maps such as those generated for the Goleta Beach County Park delineated POI were created for each of the POIs in this pilot project (Appendix).

Figure 4: Goleta Beach polygon used for analysis.

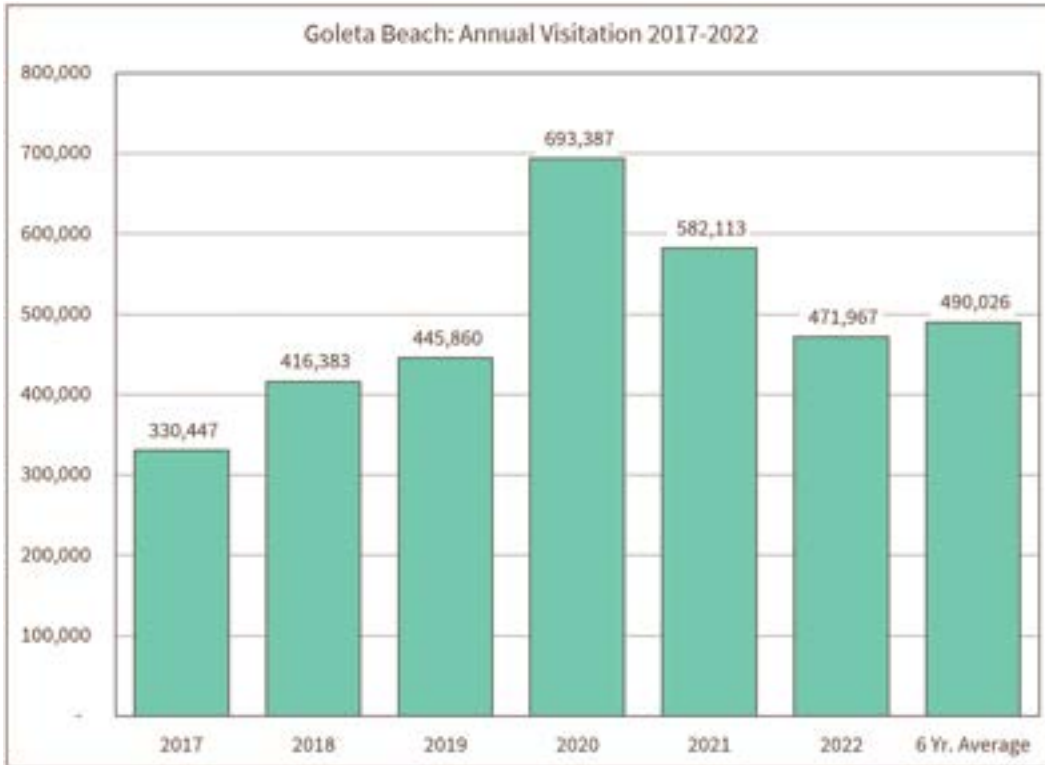

Figure 5: Visitation to Goleta Beach from 2017-2022.

Figure 6: Graph of Total Visitation from 2017-2022 to Goleta Beach by home county.

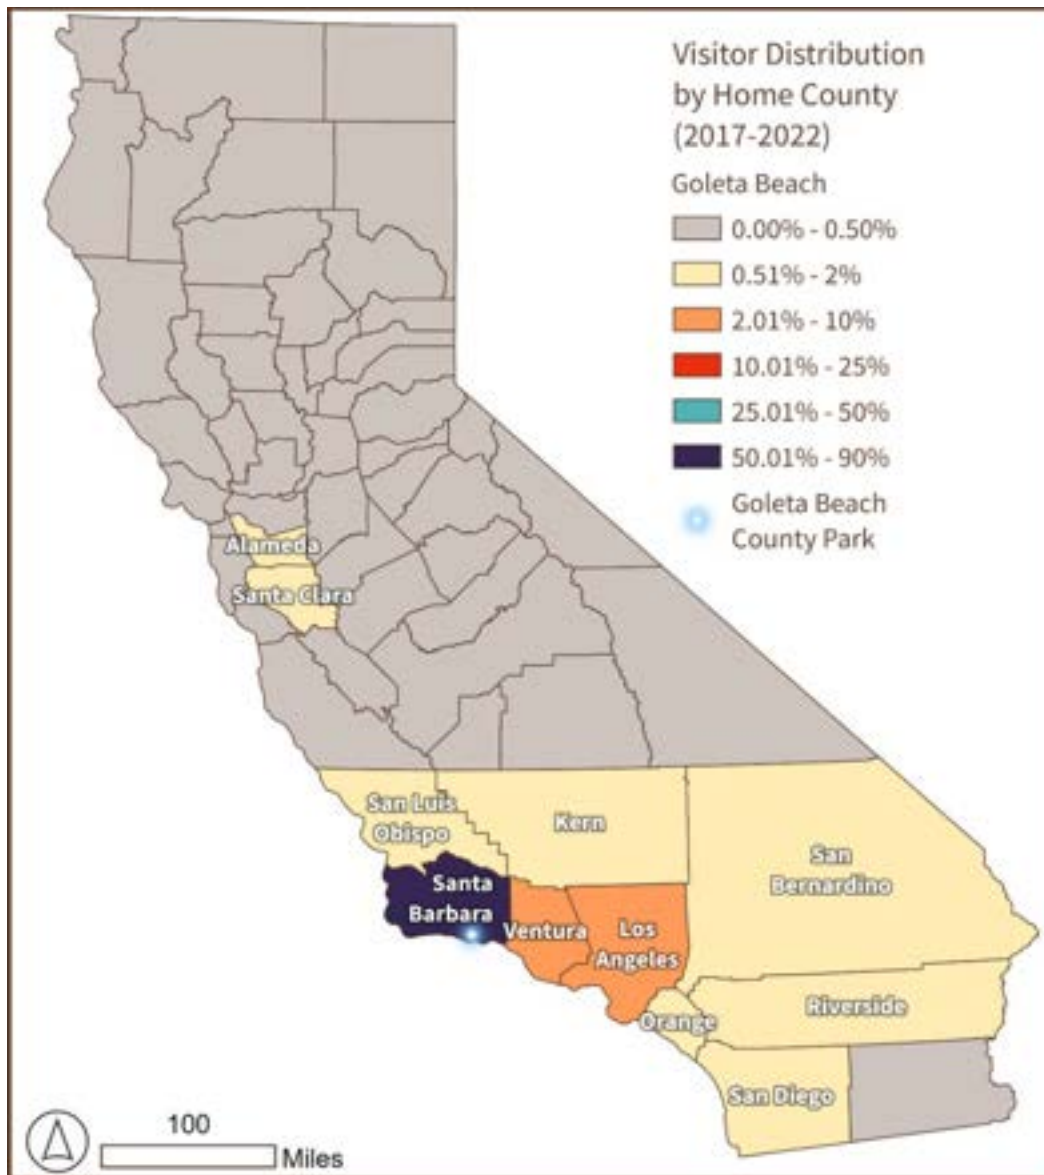

Figure 7: Map of Goleta Beach Visitation by home county from 2017-2022. During this time period, Goleta Beach had a total of nearly 3 million visitors.

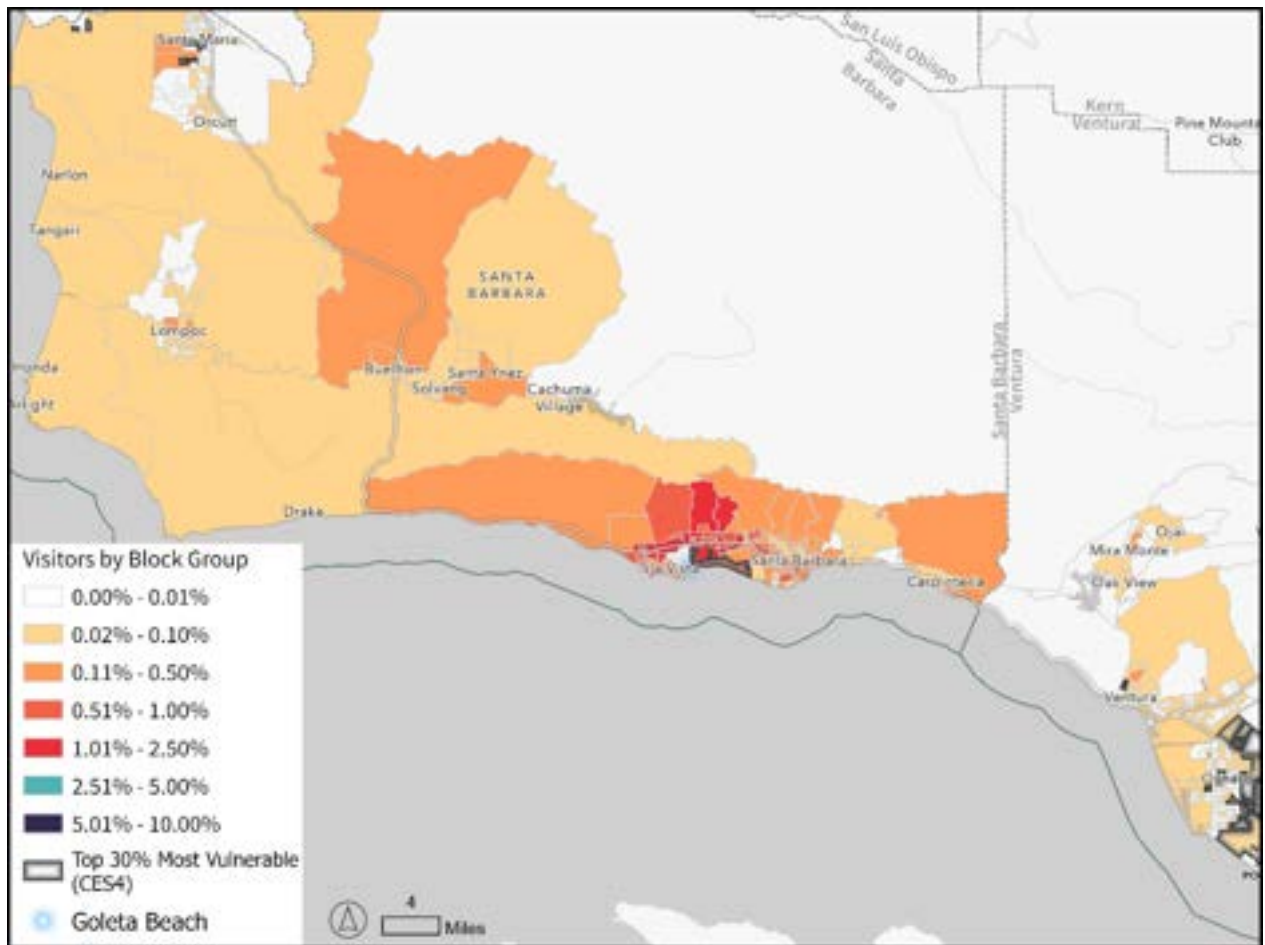

Figure 8: Map of Goleta Beach visitation by home census block group. During this time period, Goleta Beach had a total of nearly 3 million visitors.

Figure 9: Goleta Beach visitation by home census block group demographics. During this time period, Goleta Beach had a total of nearly 3 million visitors.

Case Study 2: Lechuza Beach

Lechuza Beach (Figure 10), located in the coastal city of Malibu, California, is a small yet significant site within the region's coastal geography. Spanning approximately 4.5 acres, this beach is under the management of the MRCA. Despite the absence of amenities such as restrooms and lifeguards, Lechuza Beach remains a popular destination attracting a diverse array of visitors, many of whom come from outside the local region (Malibu Pacific Palisades Chamber of Commerce, 2024). Malibu, known for its stunning 21-mile coastline, attracts an average of 13 million visitors annually (Malibu Pacific Palisades Chamber of Commerce, 2024), with a substantial portion being non-residents of the immediate area (Niche, 2024). Los Angeles County, with a population exceeding 10 million people—about a quarter of California's total population—is thought to serve as a significant source of visitors to Malibu's beaches (Bureau, 2020; United States Census Bureau, 2020).

Figure 10: Lechuza Beach in Malibu, California spans 4.5 acres and is managed by Mountains Recreation and Conservation Authority (MRCA).

To understand beach usage patterns, the POI (Point of Interest) polygon was delineated to encompass the beach and the adjacent street parking areas that serve Lechuza Beach (Figure 11). Visitation statistics were calculated and analyzed for the period from January 1, 2017, to December 31, 2022. During this six-year span, approximately 2,055,475 people visited the beach, averaging about 940 visitors per day or ~340,000 people per year (Figure 12). The average duration of stay was 1.25 hours, with July identified as the peak month for visitation. The busiest day of the week was Sunday, and the busiest hour was 1:00PM.

Figure 11: The POI boundaries drawn around Lechuza Beach, Malibu, California includes parking along Broad Beach Road and the Pacific Coast Highway (PCH).

While the majority of visitors originate from Los Angeles County, accounting for 1.2 million visitors from 2017 to 2022, over 500,000 visitors come from Ventura County (Figures 13 and 14). Additionally, 15% of visitors to Lechuza Beach have their home origin in census tracts that rank in the top 30% most vulnerable according to California EnviroScreen 4.0, with significant visitation from several underserved communities in Ventura County (Figure 15). An interactive map of visitation patterns to Lechuza Beach can be found [here](https://csucigis.maps.arcgis.com/apps/instant/interactivelegend/index.html?appid=6d4132db9f2348bcb115d5f6d8c6907d) (<https://csucigis.maps.arcgis.com/apps/instant/interactivelegend/index.html?appid=6d4132db9f2348bcb115d5f6d8c6907d>).

The racial and ethnic breakdown of visitors to this beach, based on their census block group distribution, is 48% white, 32% Hispanic or Latino/a/x/e, 11% Asian, 3.5% Black, and 5.5% other single race or multiple races (non-Hispanic; Figure 16). The appeal of Malibu's coastal areas, including Lechuza Beach, to visitors from underserved regions underscores the importance of accessible natural recreational spaces for diverse populations seeking respite from urban environments.

Figure 12: Annual visitation to Lechuza Beach in Malibu, California from 2017-2022.

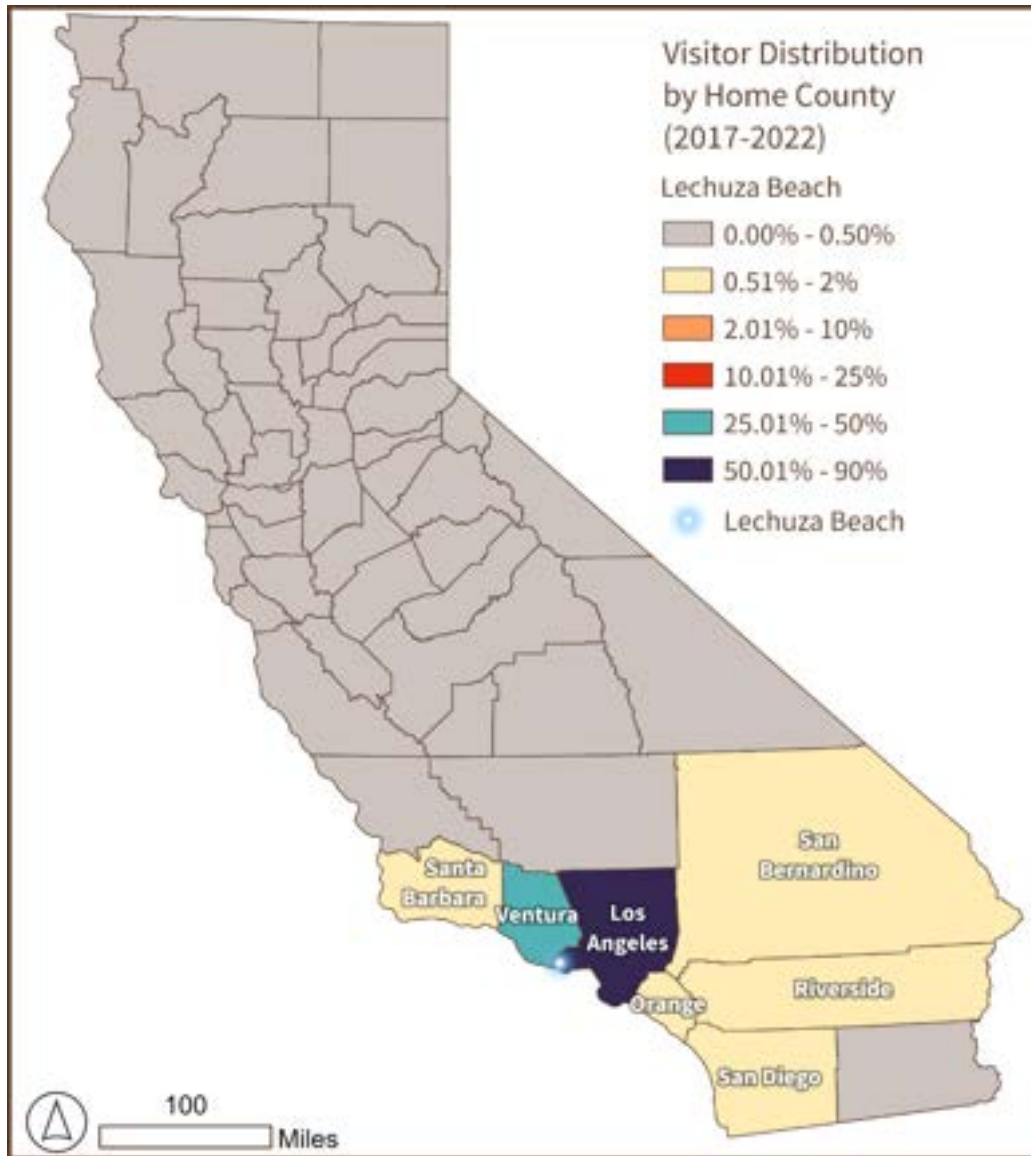

Figure 13: This map shows the county of origin for visitors to Lechuza Beach in Malibu, California.

Figure 14: This table shows the county of origin for visitors to Lechuza Beach in Malibu, California.

Figure 16: Race/Ethnicity of visitors to Lechuza Beach from 2017-2022 as represented by their census block group distribution.

Visitation Comparison of in-the-field counts and cellphone location generated visitation data.

Beach visitor counts estimated through the BSA from 2017 to 2022 were compared with visitation estimates derived from cellphone location data from 2017 to 2022 at the 32 overlapping beach polygons (Figure 17). The overall Pearson correlation coefficient was 0.34, indicating a moderate linear relationship between the two data sets. The scale relationship (BSA/cellphone-derived location data) was 0.29, meaning that the cellphone-derived data series counted approximately 3 visitors for every one person counted in the BSA on average. This relationship aligns well with the results of other studies (Merrill et al., 2020; Monz et al., 2019; Tsai et al., 2023), confirming the utility and limitations of cellphone-derived location data for estimating beach visitation.

Figure 17: Cellphone location data visitation estimates vs in-the-field beach visitor counts completed as part of the Beach Sustainability Assessment (BSA). Each point represents an observation of BSA counts and a cellphone-derived location data estimate based on a 3-hour average window (1 hour before and after the recorded BSA survey time). The black line is 1:1 relationship and the red line a linear regression.

How well these sources of visitation related varied by beach. Figure 18 shows three delineated beach areas with the most observations overlapping the cellphone-derived location data. Table 5 shows the correlation coefficient for each beach in the sample.

Figure 18: Graphical representation of the correlation between beach visitors estimated using in-the-field counts and cellphone derived visitation estimates.

Table 5: Correlation coefficient when comparing beach visitors estimated using in-the-field counts and cellphone derived visitation estimates.

Discussion

This pilot project aimed to explore the potential of commercially available cellphone data sources to provide new insights into beach use (visitation) and users. Specifically, this project focused on understanding how these data could be integrated into a visitor use monitoring program, with an emphasis on identifying patterns among diverse and disadvantaged communities. The pilot project revealed both the promise and limitations of using cellphone data for beach use/user information, offering valuable lessons for future integration efforts. Below, we discuss the practical considerations and implications of our findings.

With considerable technical staff effort, including coding, data management, and GIS integration, summaries and maps about visitation and visitor profiles using this single source of information across many locations and times were generated (Appendix). The scale and granularity of this analysis, based on passively collected data, are not feasible using traditional methods such as on-the-ground spot counts or periodic lifeguard counts. Additionally, continuously collected data allows for opportunistic studies of changes in areas of interest, providing an advantage over bespoke on-the-ground information collections that are limited in their temporal and spatial representation.

For event studies, such as beach and coastal trail closures, COVID-19 impacts, and oil spills, the use of cellphone data provides a historic record to reference after the event. While this project only leveraged a few dimensions of the data, there is great promise in using the more granular hourly-based information to understand changes in inter-day use. This includes studying the relationship between changes in beach and coastal trail conditions and visitation related to beach erosion and sea-level rise impacts, water quality-related beach closure effects on visitation, and extreme heat refugia beach visitation from inland communities.

Visitor origin information revealed more detailed data about beach use, including identifying distinct Beach User Market Areas (BUMAS) for individual POIs. Many of these BUMAs extend across large regional geographies and are generally much larger than suggested by previous anecdotal evidence. Visitors traveled from great distances and from numerous disadvantaged areas to visit the beaches analyzed in this pilot project. Capturing this wide beneficiary geography in a scalable and passively collected manner opens many potentially fruitful avenues for research and management. This data can help improve visitor-serving amenities necessary to visitors that may not live near the coast such as restrooms, parking and daily tide information.

The Cellphone Data Working Group faced significant challenges in using cellular device location datasets for this pilot project. The first challenge was navigating an opaque and rapidly changing market for commercial vendors and products. The procurement stage was more time-consuming and frustrating than anticipated. Vendors offered varied products for niche needs like transportation volume or retail foot traffic, but none provided the on-the-ground validation evidence needed. Pricing and delivery structures were confusing, with options ranging from custom data deliveries to software-as-a-service (SaaS) self-operated portals. Future users should consider this step a substantial effort.

Additionally, the data represents a sample of people who visited the defined areas, generated by a proprietary vendor algorithm that translates cellphone location information into the number of users; it is not a one-to-one relationship. Like other social science surveys and observational methods, this approach may introduce biases and limitations in representing population-level behaviors. The device location data comes from smartphone apps, which may over- or underrepresent certain user types. Changes in user behavior and privacy settings can alter the sample over time, but users do not receive this raw data, and the specific apps providing information at any given time remain protected as commercial information. These factors make inferences based on cellular device location data prone to potential pitfalls without proper calibration and validation work. While evidence for the efficacy of cellphone-derived location data in estimating visitation at parks and beaches is growing, local information is crucial for understanding specific concerns or differences in data application.

Lastly, the demographic analysis of beach visitors in this pilot project revealed several challenges. Initially, the demographics inferred from the cellphone-derived location data relied on 2010 US Census Bureau information regarding the origin home census block group of the device. However, accurately representing individuals identifying as “Hispanic” posed challenges, as ethnicity was not distinguished from race in the original 2010 Census data provided by AirSage, the vendor. The introduction of 2020 Census Bureau demographic information improved this process by better delineating those identifying as Hispanic from other racial categories. Significant effort was invested in cross-walking census information into desired categories. It is important to note that no individual perfectly reflects the average demographics of their census block group. Additionally, variations in demographics within a block group may introduce errors when extrapolating these data to beach users. While the impact of these errors remains unclear, it warrants attention and comparison to other methods of estimating visitor demographics. The available definitions of disadvantaged communities for census geography were extensive, with each option addressing slightly different combinations of factors. The optimal choice depends on the specific needs of the use case, with some options explicitly linked to state or federal funding, while others consider additional environmental stressors.

This pilot project effort highlighted the need for additional and varied on-the-ground visitation counts and surveys. The variability observed in the relationship between the cellphone-derived location data and the BSA counts underscores the importance of understanding the factors influencing this relationship for successfully integrating cellphone-derived location data into monitoring protocols. Conducting more observational counts at beaches of interest, focusing on locations with optimal geographic settings for accurate data collection (such as controlled entrances and limited space), would help understand the utility and efficacy of each effort. Instead of solely relying on snapshot counts to determine the number of people at a place at a given time, as done with the BSA data collection, the plan is to conduct more comprehensive 'all-day' counts capturing observations of the most conceptualized visitation metric: unique daily visitors, akin to a gate count. With these data, the intention is to explore the development of models based on identified relationships,

complemented by other on-the-ground collections nationwide, to create more accurate and validated visitor use prediction models for these beaches.

The pilot project revealed the need to develop an integrated regional monitoring program that addresses data acquisition and data sharing protocols, as well as data hosting, accessibility, transparency, and usability. Currently, there are no formal long-term agreements involving multiple agency coordination and collaboration that detail information sharing, agency responsibilities, program funding, or institutional needs. Current data collection and analysis efforts are undertaken on an "opportunity" basis, supported by grant funding available for individual projects.

To improve the situation, it is essential to establish a structured framework for ongoing regional collaboration. This framework should include clear guidelines for data sharing and acquisition, ensuring that all participating agencies have access to necessary data while maintaining high standards of data security and privacy. Additionally, creating a centralized data hosting platform would facilitate easier access and analysis of shared data, promoting transparency and improving the usability of the information.

Moreover, securing stable and long-term funding is crucial for sustaining these efforts. This could involve seeking commitments from local, state, and federal agencies, as well as exploring partnerships with private organizations and non-profits interested in coastal management and conservation. By developing a robust, integrated monitoring program, agencies can better manage coastal resources and address the challenges identified during the pilot project.

Conclusion

This pilot project elucidates the methodologies employed and key challenges encountered in utilizing private vendor mobility data for beach visitation analysis. It underscores the considerable expense and complexity associated with accessing and leveraging such data, as well as the limitations inherent in current demographic information provided by the US Census Bureau. Moreover, it emphasizes the necessity of trained research and technical personnel to conduct robust data analysis in this domain.

Despite these challenges, the successful integration of vendor data records and updated census files within a Geographic Information System (GIS) interface signifies a promising advancement. Initial analyses of selected data outputs demonstrate the potential for producing various data analysis products, including GIS mapping and visualization, to enhance our comprehension of beach and coastal use dynamics. Such insights hold promise for informing policy, planning, and decision-making processes.

Researchers and managers involved in the pilot project advocate for increased investment by public agencies in acquiring and analyzing cellphone location data. This investment is crucial for further elucidating barriers and constraints to coastal beach access in southern California, particularly for those underrepresented and disadvantaged communities, thereby fostering a more inclusive approach to beach visitation and utilization. Additional data collection and

analysis is warranted as part of larger research efforts to assist in developing a better understanding of the range of ecosystem services provided by 'the beach' to society.

However, it is paramount to underscore that this data source must be complemented by and validated through expanded and improved on-the-ground beach counts and surveys. These efforts, including beach use counts and intercept surveys conducted at regular intervals, must be integrated into a comprehensive, multi-year data collection, research, and monitoring program.

Such a program, spearheaded by a consortium of public agencies and university partners, would facilitate the systematic collection and analysis of social science and socio-economic information pertaining to coastal public beach access and use, thus fostering a fuller and more nuanced understanding of beach use and beach user needs, preferences, and behavior.
